Description

vwls estimates a linear regression using variance-weighted least squares. It differs from ordinary least-squares (OLS) regression in that it does not assume homogeneity of variance, but requires that the conditional variance of *depvar* be estimated prior to the regression. The estimated variance need not be constant across observations. vwls treats the estimated variance as if it were the true variance when it computes standard errors of the coefficients.

You must supply an estimate of the conditional standard deviation of *depvar* to vwls by using the sd(*varname*) option, or you must have grouped data with the groups defined by the *indepvars* variables. In the latter case, vwls treats all *indepvars* as categorical variables, computes the mean and standard deviation of *depvar* separately for each subgroup, and computes the regression of the subgroup means on *indepvars*.

regress with analytic weights can be used to produce another kind of "variance-weighted least squares"; see *Remarks and examples* for an explanation of the difference.

Quick start

Variance-weighted least-squares regression of y on x1 and x2, with the estimated conditional std. dev. of y stored in sd

vwls y1 x1 x2, sd(sd)

Add categorical variable a using factor-variable syntax

vwls y1 x1 x2 i.a, sd(sd)

Same as above, but restrict the sample to cases where v is greater than 1

vwls y1 x1 x2 i.a if v>1, sd(sd)

Variance-weighted least-squares regression for grouped data with subgroups defined by a2 and a3 vwls y2 i.a2 i.a3

Syntax

Description options Model noconstant suppress constant term sd(varname) variable containing estimate of conditional standard deviation Reporting set confidence level: default is level(95) level(#) display_options control columns and column formats, row spacing, line width, display of omitted variables and base and empty cells, and factor-variable labeling display legend instead of statistics <u>coefl</u>egend indepvars may contain factor variables; see [U] 11.4.3 Factor variables. bootstrap, by, collect, jackknife, rolling, and statsby are allowed; see [U] 11.1.10 Prefix commands.

Weights are not allowed with the bootstrap prefix; see [R] bootstrap.

vwls depvar indepvars [if] [in] [weight] [, options]

fweights are allowed; see [U] 11.1.6 weight.

coeflegend does not appear in the dialog box.

See [U] 20 Estimation and postestimation commands for more capabilities of estimation commands.

Options

Model

noconstant; see [R] Estimation options.

sd(varname) is an estimate of the conditional standard deviation of *depvar* (that is, it can vary observation by observation). All values of *varname* must be > 0. If you specify sd(), you cannot use fweights.

If sd() is not given, the data will be grouped by *indepvars*. Here *indepvars* are treated as categorical variables, and the means and standard deviations of *depvar* for each subgroup are calculated and used for the regression. Any subgroup for which the standard deviation is zero is dropped.

Reporting

level(#); see [R] Estimation options.

display_options: noci, nopvalues, noomitted, vsquish, noemptycells, baselevels, allbaselevels, nofvlabel, fvwrap(#), fvwrapon(style), cformat(%fmt), pformat(%fmt), sformat(%fmt), and nolstretch; see [R] Estimation options.

The following option is available with vwls but is not shown in the dialog box:

coeflegend; see [R] Estimation options.

Remarks and examples

The vwls command is intended for use with two special—and different—types of data. The first contains data that consist of measurements from physical science experiments in which all error is due solely to measurement errors and the sizes of the measurement errors are known.

You can also use variance-weighted least-squares linear regression for certain problems in categorical data analysis, such as when all the independent variables are categorical and the outcome variable is either continuous or a quantity that can sensibly be averaged. If each of the subgroups defined by the categorical variables contains a reasonable number of subjects, then the variance of the outcome variable can be estimated independently within each subgroup. For the purposes of estimation, vwls treats each subgroup as one observation, with the dependent variable being the subgroup mean of the outcome variable.

The vwls command fits the model

$$y_i = \mathbf{x}_i \boldsymbol{\beta} + \varepsilon_i$$

where the errors ε_i are independent normal random variables with the distribution $\varepsilon_i \sim N(0, \nu_i)$. The independent variables \mathbf{x}_i are assumed to be known without error.

As described above, vwls assumes that you already have estimates s_i^2 for the variances ν_i . The error variance is not estimated in the regression. The estimates s_i^2 are used to compute the standard errors of the coefficients; see *Methods and formulas* below.

In contrast, weighted OLS regression assumes that the errors have the distribution $\varepsilon_i \sim N(0, \sigma^2/w_i)$, where the w_i are known weights and σ^2 is an unknown parameter that is estimated in the regression. This is the difference from variance-weighted least squares: in weighted OLS, the magnitude of the error variance is estimated in the regression using all the data.

Example 1

An artificial, but informative, example illustrates the difference between variance-weighted least squares and weighted OLS.

We measure the quantities x_i and y_i and estimate that the standard deviation of y_i is s_i . We enter the data into Stata:

. use https://www.stata-press.com/data/r19/vwlsxmpl

. list

	x	У	s
1.	1	1.2	.5
2.	2 3	1.9	.5
з.	3	3.2	1
4.	4	4.3	1
5.	5	4.9	1
6.	6	6.0	2
7.	7	7.2	2
8.	8	7.9	2

4

Because we want observations with smaller variance to carry larger weight in the regression, we compute an OLS regression with analytic weights proportional to the inverse of the squared standard deviations:

. regress y x (sum of wgt is	0	2)]					
Source	SS	df	MS	Numb	er of obs	=	8
				- F(1,	6)	=	702.26
Model	22.6310183	1	22.6310183	3 Prob) > F	=	0.0000
Residual	.193355117	6	.032225853	8 R-sc	luared	=	0.9915
				- Adj	R-squared	=	0.9901
Total	22.8243734	7	3.26062477	7 Root	MSE	=	.17952
У	Coefficient	Std. err.	t	P> t	[95% cc	onf.	interval]
x	.9824683	.0370739	26.50	0.000	.891751	17	1.073185
_cons	.1138554	.1120078	1.02	0.349	160217	79	.3879288

If we compute a variance-weighted least-squares regression by using vwls, we get the same results for the coefficient estimates but very different standard errors:

. vwls y x, so	l(s)						
Variance-weighted least-squares regression Number of obs =						8	
Goodness-of-fit chi2(6) = 0.28 Model chi2(1) =					33.24		
Prob > chi2		= 0.9996		Prob >	chi2	=	0.0000
у	Coefficient	Std. err.	Z	P> z	[95%	conf.	interval]
x _cons	.9824683 .1138554	.170409 .51484	5.77 0.22	0.000 0.825	.6484 8952		1.316464 1.122923

Although the values of y_i were nicely linear with x_i , the vwls regression used the large estimates for the standard deviations to compute large standard errors for the coefficients. For weighted OLS regression, however, the scale of the analytic weights has no effect on the standard errors of the coefficients—only the relative proportions of the analytic weights affect the regression.

If we are sure of the sizes of our error estimates for y_i , using vwls is valid. However, if we can estimate only the relative proportions of error among the y_i , then vwls is not appropriate.

Example 2

Let's now consider an example of the use of vwls with categorical data. Suppose that we have blood pressure data for n = 400 subjects, categorized by gender and race (black or white). Here is a description of the data:

```
. use https://www.stata-press.com/data/r19/bp
```

```
. table gender race, statistic(mean bp) statistic(sd bp) statistic(freq)
```

> nformat(%8.1f)

	White	Race Black	Total
Gender			
Female			
Mean	117.1	118.5	117.8
Standard deviation	10.3	11.6	10.9
Frequency	100.0	100.0	200.0
Male			
Mean	122.1	125.8	124.0
Standard deviation	10.6	15.5	13.3
Frequency	100.0	100.0	200.0
Total			
Mean	119.6	122.2	120.9
Standard deviation	10.7	14.1	12.6
Frequency	200.0	200.0	400.0

Performing a variance-weighted regression using vwls gives

. vwls bp gender race Variance-weighted least-squares regression Number of obs 400 = Goodness-of-fit chi2(1) = 0.88 Model chi2(2) = 27.11 Prob > chi2 = 0.3486 Prob > chi2 = 0.0000 bp Coefficient Std. err. z P>|z| [95% conf. interval] 1.170241 5.02 0.000 3.582892 gender 5.876522 8.170151 race 2.372818 1.191683 1.99 0.046 .0371631 4.708473 _cons 116.6486 .9296297 125.48 0.000 114.8266 118.4707

By comparison, an OLS regression gives the following result:

. regress bp g	gender race						
Source	SS	df	MS	Numbe	r of obs	=	400
				- F(2,	397)	=	15.24
Model	4485.66639	2	2242.83319	9 Prob	> F	=	0.0000
Residual	58442.7305	397	147.210908	3 R-squ	ared	=	0.0713
				- Adj R	-squared	=	0.0666
Total	62928.3969	399	157.71528	3 Root	MSE	=	12.133
bp	Coefficient	Std. err.	t	P> t	[95% co:	nf.	interval]
gender	6.1775	1.213305	5.09	0.000	3.79219	4	8.562806
race	2.5875	1.213305	2.13	0.034	.202193	8	4.972806
_cons	116.4862	1.050753	110.86	0.000	114.420	5	118.552

Note the larger value for the race coefficient (and smaller *p*-value) in the OLS regression. The assumption of homogeneity of variance in OLS means that the mean for black men pulls the regression line higher than in the vwls regression, which takes into account the larger variance for black men and reduces its effect on the regression.

Stored results

vwls stores the following in e():				
Scalars e(N) e(df_m) e(chi2) e(df_gf) e(chi2_gf) e(rank)	number of observations model degrees of freedom model χ^2 goodness-of-fit degrees of freedom goodness-of-fit χ^2 rank of e(V)			
Macros e(cmd) e(cmdline) e(depvar) e(properties) e(predict) e(asbalanced) e(asobserved)	<pre>vwls command as typed name of dependent variable b V program used to implement predict factor variables fvset as asbalanced factor variables fvset as asobserved</pre>			
Matrices e(b) e(V) Functions e(sample)	coefficient vector variance–covariance matrix of the estimators marks estimation sample			

In addition to the above, the following is stored in r():

Matrices

r(table) matrix containing the coefficients with their standard errors, test statistics, p-values, and confidence intervals

Note that results stored in r() are updated when the command is replayed and will be replaced when any r-class command is run after the estimation command.

Methods and formulas

Let $\mathbf{y} = (y_1, y_2, \dots, y_n)'$ be the vector of observations of the dependent variable, where n is the number of observations. When sd() is specified, let s_1, s_2, \dots, s_n be the standard deviations supplied by sd(). For categorical data, when sd() is not given, the means and standard deviations of y for each subgroup are computed, and n becomes the number of subgroups, \mathbf{y} is the vector of subgroup means, and s_i are the standard deviations for the subgroups.

Let $\mathbf{V} = \text{diag}(s_1^2, s_2^2, \dots, s_n^2)$ denote the estimate of the variance of \mathbf{y} . Then the estimated regression coefficients are

$$\mathbf{b} = (\mathbf{X}'\mathbf{V}^{-1}\mathbf{X})^{-1}\mathbf{X}'\mathbf{V}^{-1}\mathbf{y}$$

and their estimated covariance matrix is

$$\widehat{\operatorname{Cov}}(\mathbf{b}) = (\mathbf{X}'\mathbf{V}^{-1}\mathbf{X})^{-1}$$

A statistic for the goodness of fit of the model is

$$Q = (\mathbf{y} - \mathbf{X}\mathbf{b})' \, \mathbf{V}^{-1}(\mathbf{y} - \mathbf{X}\mathbf{b})$$

where Q has a χ^2 distribution with n - k degrees of freedom (k is the number of independent variables plus the constant, if any).
